Abstract

Recent advances in Model-based fMRI approaches enable researchers to investigate hypotheses about the time course and latent structure in data that were previously inaccessible. Cognitive models, especially when validated on multiple datasets, allow for additional constraints to be marshalled when interpreting neuroimaging data. Models can be related to BOLD response in a variety of ways, such as constraining the cognitive model by neural data, interpreting the neural data in light of behavioural fit, or simultaneously accounting for both neural and behavioural data. Using cognitive models as a lens on fMRI data is complementary to popular multivariate decoding and representational similarity analysis approaches. Indeed, these approaches can realise greater theoretical significance when situated within a model-based approach.

Highlights

Cognitive models can formalise theories to make assumptions and predictions clearer.

Cognitive models offer additional constraints when interpreting the BOLD response.

Models can go from behaviour to BOLD, vice versa, or address both simultaneously.

Model-based approaches can incorporate pattern similarity and decoding approaches.
Introduction

Memory by definition involves processes that extend over time and involve generalisation or similarity structure. Formal models offer a way to characterise these processes and better understand their brain basis. As I will review, there are a number of cases in which fMRI researchers could not have made an advance without a model-based analysis approach.

Models can play a number of constructive roles in psychology, neuroscience and science more broadly. One function is simply organising one's ideas and making assumptions clear. Each step needs to be detailed, which can reduce wiggle room relative to purely verbal theories. Whatever wiggle room is left (e.g., tuneable parameters) is made explicit.

As a consequence, what is predicted under different circumstances is made clear. Rather than debate what a theory predicts, a model can be simulated. For example, early work showing an advantage in processing category prototypes led researchers to believe that abstract prototypes were stored in memory, but subsequent work demonstrated such effects were compatible with exemplar models that store no abstractions in memory [1]. More recently, models have played a related role in the design and interpretation of fMRI studies of memory [2,3]. Models can play a constructive role in directing empirical investigations.

Science often progresses by evaluating competing theoretical accounts. Models afford the possibility of model comparison in which competing accounts can be pitted against one another and the model that performs best can be favoured. For example, Mack and colleagues [4] formally evaluated whether the representations in an exemplar or prototype model best matched the BOLD response and found the exemplar model was more consistent (also see [5]). Recent work evaluating whether the hippocampus learns to associate objects and words incrementally or in an all-or-none fashion used a related approach that favoured the all-or-none account [6].

Models can serve a powerful integrative role by linking seemingly disparate findings through common computational mechanisms. For example, a simple model of familiarity and recognition memory captured findings from both fMRI studies of visual categorisation and word list memory [7]. In my own work, the same clustering approach to understanding human learning has been applied to a number of fMRI studies [8–12], which helps to theoretically link studies. Recent work [13] has extended these same model mechanisms to offer an alternative explanation for place and grid cell responses in rodents and humans. This account makes novel predictions for how cell responses should change under different experimental conditions.

The aforementioned models can be considered cognitive models. These models are hypothesised to involve the same processes and representations as the human mind. Cognitive models reside at Marr’s [14] algorithmic level and are well-placed to help explain how the brain implements higher-level computations [15]. Below, I will discuss the various ways that cognitive models can be related to fMRI data.
In addition to using cognitive models, neuroscientists also use formal models as purely data analysis tools. For example, the Generalised Linear Model (GLM) itself is a formal model that has assumptions and tuneable parameters that are fit to data. Of course, the GLM is not a model of how people process and represent information. Other examples of data analysis tools include Dynamic Causal Modelling [16], techniques to measure the intrinsic or functional dimensionality of fMRI data [17], and Multi-Voxel Pattern Analysis (MVPA).

*Figure 1: The top row illustrates approaches that are not model-based in that they don’t leverage a cognitive model of the task. For example, in the top-left panel, a standard analysis might identify voxels that are more active for faces than for house stimuli, whereas in the top-right panel a decoder might try to classify whether the participant is viewing a house or a face stimulus on each trial. In the bottom row, a cognitive model is at the centre of the analysis. In the bottom-left panel, some measure from the cognitive model (which is usually fit to behavioural data), such as item familiarity, learning update, etc., is entered into the GLM. Such an analysis will identify voxels that show a similar activation profile to the model measure. In contrast, in the bottom-right quadrant, a classifier is applied to the brain to try to decode some internal measure from the cognitive model. In this case, models are favoured to the extent that their internal state is decodable [4].

MVPA decoding approaches apply a machine classifier to "mind read" from the BOLD response whether a participant, for example, is viewing a house or a face [18]. Although these are not psychological models, they can be used to make interesting behavioural predictions. For example, participants tend to have faster response times for stimuli that are further from the classifier’s decision bound, which indicates the classifier is more confident about its decision [19]. Decoding approaches can also be used to determine when people are engaging in replay [20–23]. The line between what is a cognitive model and a data analysis tool can be blurred at times.

**Linking cognitive models to the BOLD response**

In a typical task fMRI analysis, experimental conditions are contrasted with one another. For example, one may contrast voxels that are more active for face than for house stimuli. The simplest model-based analysis replace the stimulus condition with some model measure (e.g., prediction error) that varies across trials [24]. By entering this regressor (e.g., prediction error) from the cognitive model into the GLM, one can evaluate which voxels co-vary with the cognitive construct. As shown in Figure 1, both the typical contrast approach and simple model-based analyses are univariate. Instead, standard MVPA analyses start from a collection of voxels (multivariate) and aim to predict some experimental condition,
such as whether the participant is viewing a house or a face. One innovation is to make the target of decoding a model measure, such as item familiarity according to a cognitive model [4]. The four quadrants shown in Figure 1 are not an exhaustive taxonomy of how to relate models to the BOLD response (for a more complete treatment, see [25,26]).

Perhaps because it's relatively straightforward, the univariate model-based approach is most common in the field. Typically, a model is fit to behavioural data and then used as a lens on the fMRI data. For example, an associative learning model was fit to behavioural data from a task where people formed impressions of various social groups through trial-by-trial feedback [27]. The fitted model provided a GLM trial-by-trial measure of valence or prejudice for each group, which tracked activity in the anterior temporal lobe in the model-based analysis. Model-based analysis was critical for capturing changes in memory across study trials.

![Figure 2](image_url)  
*Figure 2: Panels a and b show model-based regressors for a measure of recognition strength (i.e., familiarity) and error correction (i.e., learning update). These model-based regressors track hippocampal activity at the stimulus presentation and feedback phases of trials, respectively [8]. In contrast, a standard contrast of exception-rule-following items (panels e and f) results in no statistically significant voxels, because this contrast does not track the time course of hippocampal activity.*

In a category learning study [8], a model-based analysis with a clustering model of learning was critical to capturing two time courses, one across trials and one within. This study examined the hippocampus's role in acquiring categories in which most items followed a rule but some items (exceptions) did not. A clustering model [28] was fit to the behavioural data (i.e., the learning curves) and two model-based measures were entered into the GLM, one for recognition strength or familiarity and one for error correction or learning update. As shown in Figure 2, the hippocampus tracked the model's recognition measure at stimulus presentation and the error measure at feedback presentation. Interestingly, a standard analysis contrasting exception and rule-following items found no significant difference -- the cognitive model proved critical to capturing how hippocampal response changes over the course of study trials.
The same modelling approach can also be used to localise two simultaneous processes (by using two different model-based measures) within the same phase of a trial to draw distinctions between the function of anterior and posterior hippocampus [9]. Another way to scale up this basic univariate modelling approach is to adopt an encoder approach in which the fitted cognitive model provides a number of model-based regressors to enter into the GLM with the goal of explaining the most variance possible within brain regions of interest [29]. In the encoding approach, rather than trying to identify voxels that significantly regress on some specific model-based measure (e.g., prediction error), the goal is for multiple model measures to capture the most overall variance possible in the GLM.

Other model-based work [30,31] reverses the flow of information to incorporate brain measures directly into the operation of the model to better predict behaviour. For example, Kragel and colleagues [30] used a variant of the Context Maintenance and Retrieval (CMR) model of free recall [32] that took signals from the Medial Temporal Lobe (MTL) to determine whether contextual reactivation was successful at each potential recall event. The model that incorporated the BOLD input performed better than a baseline model in predicting behaviour.

Rather than link from model to brain or brain to model, joint modelling approaches [33,34] simultaneously model the mutual constraints between behavioural and brain measures through an intermediary cognitive model. This approach can deal with multiple brain measures (e.g., fMRI and EEG) and can make predictions about missing measures based on covariance with the observed measures.

There are number of other creative ways to link cognitive models to BOLD response. One way is to link a key event, as indexed by the cognitive model, to an operation in the brain. For example, a recent study finds that prediction errors during study are predictive of later replay events [20]. In other work, a Bayesian model determined the probability that an item would be remembered, which correlated with hippocampal activity during encoding [35].

Finally, a cognitive model's fitted parameters can be related to the BOLD response instead of a trial-by-trial measure from the model. During category learning, models [28,36] predict that goal-relevant aspects of the stimuli will receive greater weight or attention. A recent study found that the learned attentional weights from category learning models fit to behaviour were predictive of how well those stimulus aspects could be decoded from the BOLD response [37]. Related, in a study exploring vmPFC-hippocampal interactions during concept learning [12], the pattern of goal-directed representation compression in vmPFC paralleled the attention weights from a model fitted to behaviour.

Models can uncover useful latent states

Models can be useful in inferring latent states that can help explain behaviour and its brain basis. One example of a latent variable are the clusters in the aforementioned learning models [28,38] which detail how related items are stored together in memory. Models operationalise these hypothesised representational structures, which can be useful in analysing BOLD response.
Inferring latent state is more complex when researchers aim to characterise complex mental operations that unfold through time [39]. One popular approach is to use hidden Markov models (HMMs) to infer what operations people are currently undertaking and using this characterisation to interpret the BOLD response [40,41].

The importance of inferring latent state is also becoming appreciated in related fields, such as reinforcement learning [42]. Many of the same conceptual issues and brain systems are implicated in these tasks as in goal-directed concept learning. For example, strategic exploration relies on hippocampal-prefrontal cooperation [43] as is found during memory tasks [12].

**Comparing model and brain representations**

In addition to MVPA decoding, multivariate pattern analysis can be used to compare proposed (e.g., model) representations and voxel representations [44]. This pattern comparison analysis is popularly known as Representational Similarity Analysis (RSA, [45]). RSA correlates two similarity matrices, one from the cognitive model and one from the brain, to assess how well the two similarity spaces align. RSA can be used as confirmatory evidence that a model provides the correct representational account of a brain region or in an exploratory fashion such as in a whole-brain searchlight analysis. One application of RSA is to compare proposed memory representations acquired by models of concept learning to brain regions thought to implement those functions [4,46]. For example, RSA analyses found that hippocampal representations of objects are modulated by changes in the task goal [10].

For an RSA to be model-based, one of the similarity matrices should be generated by a cognitive model. RSA can involve the evaluation of several cognitive models. A variety of models can be considered and the model whose representations best align with the brain can be favoured [46]. However, not all RSAs are model-based and the dividing line can be blurry. For example, technically, finding that hippocampus CA1 codes distance to a goal [47] is not model-based (because distance is specified by the task), whereas coding distance to some model quantity, such as distance to a category prototype [48], is model-based (because the prototype is specified by the fitted cognitive model). For a model-based analysis to be useful, it should add something beyond a standard analysis. Ideally, a model-based analysis would improve both data fit and our understanding of the domain. For example, a model may largely code distance to goal, but diverge in informative ways under certain circumstances that could be empirically verified and in turn deepen our understanding of the domain.

Certainly, univariate analyses can be rigorous, interesting, and motivated but not model-based. The same is true in RSA. For example, a recent study [49] used similarity matrices designed to capture perceptual or conceptual similarity to hone in on the function of perirhinal cortex and other regions. This work is exciting and valuable, but because the similarity matrices were derived from human ratings rather than generated by a model of perceptual or conceptual processing, the analysis is not model-based.

**Conclusions**
Adopting a model-based approach to fMRI analysis can offer a number of advantages. In some cases, one can evaluate hypotheses that otherwise would not be possible with a standard analysis approach. Models, which are formalised as theories, offer the hope that results will be theoretically grounded. As related models are applied across data sets, models may promote a more systematic and cohesive science. Cognitive models are well positioned to integrate findings across levels of analysis [15].

I have reviewed a number of ways to relate cognitive models to the BOLD response. Possibilities include fitting models to be behaviour and incorporating derived trial-by-trial measures into the GLM, model decoding approaches [4], using BOLD response to drive the behavioural predictions of the model, joint modelling to simultaneously address brain and behavioural measures, and RSA comparisons of model representations and BOLD response. Which approach is suitable is largely a function of the study's design and the researcher's aims.

One key question to consider is why do model-based analyses work? Models are not magical, nor guaranteed to be helpful, so why are there so many cases in which model-based analyses succeed in pulling more from the data than would be possible through a standard analysis? The answer is that models have the ability to incorporate constraints that are outside the immediate study. In my own work, models are developed over years and honed while being applied to multiple behavioural and fMRI datasets. In this sense, the models have a reality and value outside their immediate application, which is critical because a model-based analyses is only as credible as the model used.
